GUIDE

What Changes with GenAI

GenAI changes more than the application

Adding generative AI to an application can feel deceptively simple. A team can connect to a hosted model, write a prompt, and produce an impressive demonstration in a short time. But a production application is not judged by its best response in a demo. It must behave usefully and safely across a wide range of real inputs, changing data, model updates, user expectations, and operational conditions.

The fundamental difference is that a traditional software component is usually designed to behave deterministically: given the same inputs and conditions, it is expected to produce the same result. A large language model (LLM), by contrast, is probabilistic. Its output can vary, and quality is often a matter of degree rather than a simple pass or fail. This changes how teams design, test, deploy, monitor, and govern software.

The answer is not to abandon established software engineering disciplines. It is to extend them. Teams need repeatable evaluation, disciplined management of prompts and models, trustworthy data pipelines, security controls, operational visibility, and clear ownership. These practices lead naturally to two complementary disciplines: DataOps and LLMOps.

CHANGE 01

Testing and quality assurance

Measure quality, not just correctness

Traditional unit tests often compare an actual result with an exact expected value. That approach is still useful for deterministic parts of an AI-enabled application, but it is insufficient for judging open-ended model responses. The same question may be answered in different words, while a response that looks fluent may still be incomplete, unsupported, or misleading.

PRACTICAL RESPONSES

Build a representative evaluation dataset.
Collect realistic user questions, edge cases, expected behaviors, and examples of unacceptable answers. Include normal, ambiguous, adversarial, and high-risk scenarios.

Define quality dimensions.
Evaluate factual accuracy, groundedness in approved sources, relevance, completeness, tone, policy adherence, refusal behavior, and structured-output validity as appropriate to the use case.

Use more than one evaluation method.
Combine deterministic checks (such as schema validation and required-field checks), model-assisted judging, and human review. Model judges can scale evaluation, but should themselves be calibrated against human-reviewed examples.

Run regression evaluations continuously.
Re-run the evaluation suite when prompts, retrieval settings, models, data, or application code change. Compare results with a baseline and investigate meaningful regressions before release.

Set release thresholds and escalation rules.
Define minimum acceptable performance for critical dimensions. Averages can hide serious failures, so track high-severity errors separately and require human approval where the impact warrants it.

The goal is not to prove that an LLM is always correct. It is to establish measurable evidence that the application performs within defined quality and risk boundaries for its intended purpose.

CHANGE 02

Prompt and model management

Version, test, and release them like code

A prompt is not merely text typed into an API call. It shapes application behavior and can be as consequential as application logic. Model selection, system instructions, parameters, tool definitions, and retrieval configuration also influence outcomes. In addition, a model provider may change or retire a model.

PRACTICAL RESPONSES

Keep prompts and configuration under version control.
Store them alongside application code or in a controlled registry. Require review, document intent, and make changes traceable.

Record the complete execution configuration.
Capture the model identifier or version where available, parameters, prompt version, tool schema, retrieval configuration, and relevant application version.

Separate environments and control promotion.
Test changes in development and staging before production. Promote a known, evaluated configuration rather than editing production prompts informally.

Treat model upgrades as releases.
Evaluate a candidate model against the same benchmark and representative production cases. Compare quality, latency, cost, safety, and compatibility before switching.

Provide rollback capability.
Keep a known-good prompt and model configuration available so the team can restore service if a change causes unacceptable behavior.

CHANGE 03

Architecture

Design for retrieval, tools, latency, and failure

GenAI applications often introduce retrieval-augmented generation (RAG), vector databases, chunking and embedding pipelines, tool or function calling, and multi-step orchestration. Model calls can also be slower and less predictable than local application calls. A design that works in a small prototype may become fragile when requests, documents, or workflow complexity increase.

PRACTICAL RESPONSES

Make components explicit.
Separate ingestion, document processing, indexing, retrieval, prompt assembly, model invocation, tool execution, and response validation where doing so improves maintainability and observability.

Design for timeouts and transient failures.
Use bounded retries with backoff, timeouts, circuit breakers, and clear handling for provider outages. Avoid retry loops that multiply cost or duplicate consequential actions.

Validate tool calls independently.
Treat model-proposed arguments as untrusted input. Validate types, ranges, permissions, and business rules in application code before executing a tool.

Use asynchronous processing where appropriate.
For long-running tasks, consider queues, background jobs, progress indicators, and resumable workflows rather than making every user wait on a single synchronous request.

Set explicit limits.
Control context size, retrieved-document count, tool-call count, execution time, and maximum spend per request or workflow.

Keep deterministic logic outside the model when possible.
Use conventional code for calculations, authorization, transaction handling, and rules that require exact outcomes. Let the model interpret or assist, not silently replace critical controls.

CHANGE 04

New failure modes

Contain errors before they reach users

An AI feature can fail without throwing an exception. It may invent a fact, ignore a constraint, produce malformed JSON, refuse a valid request, or give inconsistent answers. These failures can be difficult to spot because the response may sound confident and well written.

PRACTICAL RESPONSES

Validate outputs against contracts.
When a workflow expects structured data, validate it against a schema and reject, repair, or safely handle invalid output.

Ground answers in evidence.
For knowledge-based tasks, retrieve approved source material, instruct the model to use it, and check that the answer is supported. Show citations or source links when they help users verify claims.

Design safe fallback paths.
If retrieval is weak, a tool fails, or confidence is insufficient, ask a clarifying question, provide a limited response, route to a human, or explain that the system cannot complete the task.

Use human approval for consequential actions.
Require confirmation before sending external messages, changing records, making purchases, or taking other actions with material impact.

Analyze failure patterns.
Classify incidents by cause—such as retrieval miss, stale data, prompt ambiguity, model behavior, tool failure, or policy gap—and feed the findings into the evaluation suite.

CHANGE 05

Security and safety

Treat context and model actions as untrusted

Prompt injection, sensitive-data exposure, unsafe tool use, and excessive agent permissions create risks that do not map neatly to conventional input validation alone. A model may read untrusted documents or web pages that contain instructions intended to manipulate its behavior. It may also be connected to tools that can access data or change systems.

PRACTICAL RESPONSES

Apply least privilege.
Give each service and tool only the permissions it needs. Prefer narrow, purpose-built operations over broad access to databases, file systems, or business systems.

Enforce authorization outside the model.
The application—not the LLM—must decide whether a user is allowed to access a record or perform an action.

Separate instructions from untrusted content.
Clearly delimit retrieved text and user-provided material. Treat their contents as data, not as trusted instructions, and test against prompt-injection attempts.

Minimize and protect sensitive data.
Avoid sending unnecessary personal or confidential information to model providers. Apply redaction, retention controls, encryption, access controls, and provider reviews appropriate to the data classification.

Test security as part of evaluation.
Include adversarial prompts, data-exfiltration attempts, unsafe tool requests, and cross-user data-access scenarios in pre-release and ongoing testing.

Moderate and audit high-risk workflows.
Use policy checks and human review where needed, and retain appropriate audit records without logging secrets or excessive personal data.

CHANGE 06

Cost and performance

Manage tokens, latency, and user experience together

With hosted LLMs, cost is influenced by input and output tokens, model choice, context length, and usage patterns. Latency may be measured in seconds rather than milliseconds. A technically correct answer can still create a poor product experience if it is too slow or too expensive to deliver reliably.

PRACTICAL RESPONSES

Measure cost and latency by workflow.
Track token usage, model, request type, response time, retries, and outcome so teams can identify expensive or slow paths.

Use the smallest model that meets the quality bar.
Route simple classification or extraction tasks to lower-cost models where evaluation shows they are adequate; reserve more capable models for tasks that need them.

Control context deliberately.
Retrieve only relevant passages, remove duplicate content, summarize long histories when appropriate, and set maximum context budgets.

Cache selectively.
Cache stable reference data, embeddings, or repeatable results where privacy, freshness, and correctness permit. Do not reuse answers when user-specific context makes that unsafe.

Design for perceived latency.
Use streaming, progress feedback, and clear status messages where appropriate. Set realistic timeouts and communicate when a task is still running.

Establish budgets and alerts.
Set per-feature or per-customer usage limits, monitor unusual spikes, and alert on cost or latency regressions.

CHANGE 07

Observability

Make the answer traceable

Traditional application logs may show that an API call succeeded, but not why the generated answer was wrong. To investigate an AI workflow, teams need visibility into the prompt version, model configuration, retrieved context, tool calls, intermediate steps, output, latency, token usage, and user feedback.

PRACTICAL RESPONSES

Trace each request end to end.
Use a correlation or trace identifier to connect application events, retrieval, model calls, tool execution, and downstream systems.

Capture useful diagnostic metadata.
Record versions, timings, token counts, retrieval identifiers or document references, validation results, and error categories.

Protect logged data.
Apply redaction, access restrictions, retention policies, and secure storage. Observability should not become an uncontrolled copy of sensitive prompts and documents.

Collect user feedback with context.
Allow users to report unhelpful or incorrect responses and link that feedback to the relevant trace, subject to privacy controls.

Turn incidents into tests.
When a failure is understood, add a representative case to the evaluation dataset so the same issue is less likely to recur.

CHANGE 08

Product and UX design

Help people use AI with appropriate confidence

Users may interpret fluent language as certainty. If the application does not communicate limitations, source evidence, and the status of actions, users may over-trust an answer—or lose trust after one visible mistake. The interface is therefore part of the safety and quality system.

PRACTICAL RESPONSES

Set expectations in context.
Explain what the AI feature can and cannot do at the point of use, rather than relying only on a general disclaimer.

Expose evidence where it matters.
Provide citations, source previews, or links for answers that depend on organizational knowledge.

Make correction easy.
Offer edit, retry, regenerate, and feedback controls when they help users recover from imperfect output.

Confirm consequential actions.
Show what will happen and request explicit approval before the system takes an external or irreversible action.

Design graceful failure states.
When the model cannot answer reliably, make the next safe step clear instead of presenting a fabricated or ambiguous result.

CHANGE 09

Development process and team

Make experimentation disciplined

GenAI development is iterative. Teams form a hypothesis, change a prompt or retrieval strategy, run evaluations, inspect failures, and repeat. Prototypes can be created quickly, but turning a promising demonstration into a dependable product often requires substantial work in data quality, evaluation, integration, security, and operations.

PRACTICAL RESPONSES

Define success before tuning.
Agree on user outcomes, measurable quality dimensions, risk limits, latency targets, and cost constraints before optimizing prompts.

Use a repeatable experiment cycle.
Change one meaningful factor at a time where practical, record the hypothesis and configuration, and compare results against a stable evaluation set.

Bring domain experts into evaluation.
Subject-matter experts help define what a good answer means, identify unacceptable mistakes, and review edge cases that generic metrics may miss.

Create clear ownership.
Assign responsibility for data pipelines, prompts, model configuration, evaluation, security, production monitoring, and incident response.

Treat launch as the beginning of operations.
Schedule ongoing evaluation, review feedback and drift, and maintain a process for updating data, prompts, models, and policies.

CHANGE 10

Governance and compliance

Know what the system uses and does

Organizations need to understand which data enters the system, where it comes from, which model or provider processes it, what actions the application can take, and how risks are assessed. Requirements vary by industry, geography, and use case, so governance should be proportionate to the actual risk.

PRACTICAL RESPONSES

Maintain a data and model inventory.
Document data sources, owners, classifications, processing purposes, model providers, model versions, and major system dependencies.

Record lineage and change history.
Be able to trace important outputs and releases to the relevant source data, index version, prompt, model configuration, and application release.

Perform risk reviews.
Assess privacy, security, reliability, bias, explainability, and human oversight needs before deployment and when the use case materially changes.

Define retention and access policies.
Specify what is stored, for how long, who can access it, and how deletion or correction requests are handled across source data, logs, and derived indexes.

Keep governance operational.
Integrate approvals, documentation, monitoring, and periodic reviews into the delivery lifecycle instead of treating governance as a one-time sign-off.

GUIDE

Why DataOps is essential

Build GenAI app on reliable data

Many GenAI features depend on organizational data: product documentation, policies, support records, technical manuals, customer information, or operational databases. In a RAG application, the model's answer is only as useful as the information that can be found, interpreted, and supplied to it. If source data is incomplete, duplicated, outdated, poorly structured, or incorrectly permissioned, a more capable LLM cannot reliably compensate.

DataOps applies operational discipline to the way data is collected, prepared, validated, governed, delivered, and monitored. It brings data engineering, automation, quality controls, collaboration, and repeatability together so that data products and pipelines can be maintained as production assets.

HOW DATAOPS HELPS

Reliable ingestion.
Automate collection from approved sources and detect failed, delayed, or incomplete ingestion.

Data quality checks.
Validate schema, completeness, freshness, duplication, consistency, and required metadata before data is used.

Controlled transformation and indexing.
Version document parsing, normalization, chunking, embedding, and indexing processes so changes can be tested and reproduced.

Lineage and provenance.
Track where content came from, when it was updated, how it was transformed, and which downstream indexes or applications depend on it.

Governance and access control.
Preserve source permissions where required, classify sensitive information, and prevent users from retrieving material they are not authorized to see.

Monitoring and recovery.
Monitor pipeline health, freshness, quality, and index coverage; support reprocessing and rollback when a pipeline change causes problems.

GUIDE

Why LLMOps is needed

Operationalize the model-powered application

Good data alone does not make a reliable AI application. Teams must also manage the behavior of the model and the application components around it throughout development and production. LLMOps extends operational and MLOps-style practices to LLM-based systems, with particular attention to prompts, model configurations, evaluation, retrieval behavior, orchestration, safety, cost, and ongoing monitoring.

HOW LLMOPS HELPS

Prompt and configuration lifecycle.
Version, review, test, promote, and roll back prompts and model settings.

Evaluation as a release gate.
Run repeatable offline evaluations and targeted online monitoring to detect regressions and changing behavior.

Model and provider management.
Compare candidate models, track provider changes, manage deployment configuration, and maintain fallback options where feasible.

Application tracing.
Trace prompts, retrieval, model calls, tool use, validation, latency, and cost across complete workflows.

Safety and reliability controls.
Operationalize output validation, guardrails, access checks, human approval, and safe fallback behavior.

Production optimization.
Monitor quality, usage, cost, and latency; use the evidence to improve prompts, retrieval, routing, and user experience.

LLMOps is not simply a tool for deploying a model. It is the set of repeatable practices that helps a team understand what is running, determine whether it is still performing acceptably, control changes, and respond when behavior or operating conditions change.

GUIDE

DataOps and LLMOps work together

The two disciplines solve connected but different parts of the problem. DataOps makes the information feeding the application trustworthy and operationally manageable. LLMOps makes the model-powered behavior measurable, controlled, and maintainable. Neither replaces conventional software engineering, security, or product management; they complement them.

Concern	DataOps focus	LLMOps focus
Knowledge freshness	Ingest, validate, transform, and refresh source data and indexes.	Measure whether retrieval and generated answers use relevant, current evidence.
Change management	Version data pipelines, transformations, schemas, and indexes.	Version prompts, model settings, evaluation suites, and orchestration.
Quality	Check completeness, validity, consistency, freshness, and lineage.	Evaluate answer quality, groundedness, safety, and task performance.
Security & governance	Classify data, manage permissions, lineage, retention, and provenance.	Control model access, prompt injection risks, tool permissions, output handling, and AI-specific risks.
Operations	Monitor pipeline health, failures, and data/index freshness.	Monitor model behavior, latency, tokens, cost, errors, and user feedback.

Consider an automated contract analysis and risk-flagging system. DataOps ensures that approved legal playbooks, clause libraries, and historical contract templates are current, correctly indexed, and accessible only to authorized users. LLMOps ensures that the system extracts suitable clauses, follows the intended extraction rules, outputs structured risk reports within defined quality thresholds, processes documents safely, and remains within latency and cost targets. If a risk report is wrong, traces and lineage help the team determine whether the cause was a stale legal playbook, a retrieval issue, a prompt change, or model behavior.

GUIDE

A practical path to adoption

Organizations do not need to introduce every process or platform at once. A sensible starting point is to choose one valuable GenAI use case and establish a minimum operating discipline around it.

1. **Define the use case and its risk.**
   Specify users, intended tasks, prohibited tasks, data sensitivity, consequences of error, and what success means.

2. **Establish the data foundation.**
   Identify authoritative sources, owners, permissions, freshness requirements, and quality checks. For RAG, version the ingestion and indexing pipeline.

3. **Create a baseline evaluation set.**
   Use real or representative scenarios, including edge cases and unsafe requests. Agree on quality dimensions and human review criteria.

4. **Version the system.**
   Track application code, prompts, model configuration, retrieval settings, data/index versions, and evaluation results.

5. **Instrument the workflow.**
   Add tracing and monitoring for quality signals, failures, latency, token usage, cost, and user feedback, with privacy controls.

6. **Introduce controlled releases.**
   Test changes in a non-production environment, compare against the baseline, review material regressions, and retain rollback options.

7. **Improve continuously.**
   Review incidents and feedback, refresh data, expand evaluations, and adjust prompts, retrieval, models, and UX based on evidence.

GUIDE

Conclusion

Reliability is an engineering outcome

Generative AI makes it easier to build an impressive prototype, but production quality depends on much more than the model itself. Teams must address probabilistic behavior, evaluation, prompt and model changes, retrieval architecture, security, cost, observability, user experience, and governance. Each challenge has practical engineering responses—but those responses need to work together as a repeatable operating model.

DataOps provides the disciplined data lifecycle that helps ensure the application is working with relevant, reliable, governed information. LLMOps provides the lifecycle management and operational visibility needed to evaluate, release, monitor, and improve the model-powered application. Together with sound software engineering practices, they help organizations move from experimentation to sustainable GenAI products.

The key question is no longer only "Which LLM should we use?" It is "How will we continuously manage the data, model behavior, application, and risks that determine the experience our users receive?"

ABOUT THIS GUIDE

This article is intended as a practical introduction. The appropriate DataOps and LLMOps architecture, controls, and tooling depend on the application's purpose, data sensitivity, risk profile, scale, and operating environment. The practices described here are engineering considerations, not a claim that every application requires the same implementation.
